(Dated: February 2, 2008)

Precise measurements of YbFeO₃ magnetization in the spin-reorientation temperature interval are performed. It is shown that ytterbium orthoferrite is well described by a recently developed modified mean field theory developed for ErFeO₃. This validates the conjecture about the essential influence of the rare earth ion's anisotropic paramagnetism on the magnetization behavior in the reorientation regions of all orthoferrites with $\Gamma_4 \rightarrow \Gamma_{24} \rightarrow \Gamma_2$ phase transitions.

I. INTRODUCTION

Rhombic rare-earth orthoferrites RFeO₃ with R being a rare-earth ion or an yttrium ion are magnetic insulators that provide a classic example of the second order orientation phase transitions. Orthoferrites have two magnetic subsystems: one of the rare-earth ions, and another of the iron ions. Magnetic properties of the subsystems and interaction between them depend on the external parameters, e.g. temperature, field, pressure, etc., and a series of phase transition is observed upon the parameter change.

In the temperature interval where phase transitions discussed in this work take place, the iron subsystem is ordered into a slightly canted antiferromagnetic structure exhibiting a weak ferromagnetic moment $\mathbf{F}$. The rare-earth system is paramagnetic. For all orthoferrites the antiferromagnetic structure below the Neel temperature T_N ($T_N = 620 \div 740\text{K}$) corresponds to the Γ_4 (G_x, F_z) irreducible representation with magnetic vector $\mathbf{F}$ pointing along the $\mathbf{c}$ axis of the crystal and antiferromagnetic vector $\mathbf{G}$ pointing along the $\mathbf{a}$ axis. The coordinates are chosen so that $\mathbf{c} = \hat{z}$ and $\mathbf{a} = \hat{x}$. In orthoferrites with non-magnetic rare-earth ions (R = La, Lu, or Y) the Γ_4 (G_x, F_z) configuration persists to the lowest temperatures. For many other orthoferrites a reorientation transition with the sequence Γ_4 (G_x, F_z) $\rightarrow$ Γ_{24} (G_{xz}, F_{xz}) $\rightarrow$ Γ_2 (G_z, F_x) is observed. Upon cooling vector $\mathbf{F}$ starts to rotate away from the $\mathbf{c}$ axis at temperature T_1 . Its continuous rotation towards the $\mathbf{a}$ axis happens in the $(\mathbf{a}, \mathbf{c})$ plane between temperatures T_1 and $T_2 < T_1$. Below T_2 , the system stays in the $\Gamma_2(G_z, F_x)$ phase with $\mathbf{F} \parallel \mathbf{a}$.

Although the spin reorientation region $[T_2, T_1]$ has been studied for many orthoferrites by different experimental techniques, not enough is known about the specifics of the rotation. Relevant experimental results are often incomplete, lack accuracy, tend to contradict each other, and do not correspond to either conventional Landau theory^{1,2,3} or its suggested modifications. Recently^{4,5} the temperature dependence of both $\mathbf{a}$ and $\mathbf{c}$ axis projections of the magnetic moment was measured with high accuracy for the single crystal samples

of ErFeO₃. These measurements gave the temperature dependence of the absolute value of the magnetization $M(T)$ and its rotation angle $\theta(T)$ with respect to the $\mathbf{c}$ axis in the $[T_2, T_1]$ temperature interval at zero external magnetic field. The results were in very good agreement with the proposed modified mean field model,⁴ that emphasized the anisotropy of the rare-earth ions paramagnetic susceptibility. It was conjectured that this model would be suitable for other magnetic materials with similar phase transitions.

The present study is aimed at the detailed measurements of $M(T)$ and $\theta(T)$ behavior in single crystals of YbFeO₃, that exhibit the same $\Gamma_4 \rightarrow \Gamma_{24} \rightarrow \Gamma_2$ transition, with the purpose of checking this conjecture on another material. It is shown that the modified field theory of Refs. 4,5 works well for YbFeO₃, even though in this orthoferrite the reorientation happens at an order of magnitude lower temperatures ($T \approx 8\text{K}$), than in ErFeO₃ ($T \approx 90\text{K}$), while the Neel temperature remains roughly the same $T_N \approx 630\text{K}$.

II. EXPERIMENTAL RESULTS

Measurements were performed on two single crystals of YbFeO₃. Cubic sample A, weighting 0.0485 g, was made of a single crystal grown by spontaneous crystallization in the melt-solution. Ellipsoid sample B, weighting 0.0715 g, was made of a single crystal grown by the no-crucible zone melting technique with radiation heating. The results for both samples are very similar. The temperature was varied in the 2 K to 10 K interval, and both M_a and M_c projections of the magnetic moment were measured by a Quantum Design MPMS-5S SQUID magnetometer.

The $\mathbf{M}(T)$ dependence at zero external magnetic field was found through the analysis of magnetization curves analogous to those shown in Fig. 1,2. To analyze the data we recall, that the $(H - T)$ phase diagrams in the vicinity of the $\Gamma_4 \rightarrow \Gamma_{24} \rightarrow \Gamma_2$ transition for $\mathbf{H} \parallel \mathbf{c}$ and $\mathbf{H} \parallel \mathbf{a}$ field directions are well known. According to them, as the magnetic field is swept through $H = 0$ inside the $[T_2, T_1]$

reorientation interval, a first order transition happens for both directions of the field and manifests itself as a jump of magnetization component parallel to the applied field. First order transitions also happen above T_1 for $\mathbf{H}||\mathbf{c}$ and below T_2 for $\mathbf{H}||\mathbf{a}$ orientations, while no transitions are predicted below T_2 for $H||\mathbf{c}$ and above T_1 for $H||\mathbf{a}$. In a real experiment exact orientation of the field direction is obviously impossible. A three-dimensional diagram valid for the arbitrary field direction^{4,6} shows that for a tilted field a first order transition happens at any temperature and a jump of at least one magnetic moment projection should be observed. In the case of single-domain switching that would produce a rectangular hysteresis loop.

Well-developed rectangular loops were indeed observed in experiments on ErFeO_3 outside of the reorientation interval.⁴ Inside the $[T_2, T_1]$ interval ($T_1 \approx 88\text{K}$ and $T_2 \approx 97\text{K}$ for erbium orthoferrite) they transformed into the S-shaped magnetization curves. Such modification was attributed to the multi-domain state formation, possibly connected to the abrupt change in domain wall mobility.⁷

In contrast with the case of ErFeO_3 , magnetization curves in YbFeO_3 are S-shaped at all temperatures studied here for both $\mathbf{H}||\mathbf{a}$ and $\mathbf{H}||\mathbf{c}$ field orientations. The width of the magnetization curves for the magnetic field directed along the $\mathbf{a}$ axis is larger than for the field along the $\mathbf{c}$ axis. In general, the total width of the loops is considerably larger than in the case of ErFeO_3 .⁴ In accord with the phase diagrams discussed above, magnetization curves become straight lines passing through the origin above T_1 for the $\mathbf{H}||\mathbf{a}$ orientation and below T_2 for the $\mathbf{H}||\mathbf{c}$ orientation. Their slope in these regions corresponds to the paramagnetic contribution of the yttrium ions (see Fig. 1,2). Importantly, magnetization

curves obtained for different samples are very similar. We extract the $\mathbf{a}$ and $\mathbf{c}$ projections of the bulk magnetization at zero external field by extrapolating their observed linear dependence at higher fields, $H \gtrsim 650\text{ Oe}$, by $M_{a,c}(H, T) = M_{a,c}(T) + \chi_{a,c}(T)H$ and extracting the vertical intercept $M_{a,c}(T)$. The values of $M_a(T)$ and $M_c(T)$ obtained through this procedure are shown in Fig. 3.

It is interesting to note, that while being very small everywhere, the hysteresis of S-shaped loops visibly increases in the reorientation region of YbFeO_3 . This fact is illustrated by the following measurement. First, a saturating magnetic field $H = 650\text{Oe}$ was applied either along the $\mathbf{a}$ - or along the $\mathbf{c}$ -axis. Then, the field was reduced to zero and the projection of the remnant magnetic moment $\mathbf{M}^{\text{remnant}}$ on the same axis was measured. Two series of measurements, one for $\mathbf{M}_c^{\text{remnant}}$ and another for $\mathbf{M}_a^{\text{remnant}}$ were made. The results for the $H||\mathbf{c}$ case are shown on Fig. 4. For S-shaped hysteresis loops the remnant magnetic moment grows with the width of the loop. The figure clearly demonstrates how the small hysteresis observed in the high-temperature symmetric phase $T \geq T_1$ grows inside the reorientation region and than drops to zero for $T \leq T_2$. Similar results were obtained for $H||\mathbf{a}$. This property of hysteresis loops in YbFeO_3 turns out to be useful for the determinations of the critical temperatures $T_{1,2}$: they are clearly marked by the kinks of the curve on Fig. 4 and give $T_1 = 8\text{K}$ and $T_2 = 6.6\text{K}$.

The shape of the magnetization curves and the presence or absence of hysteretic behavior depends on the quality of the samples, energy of the domain walls, etc. The observed difference between erbium and yttrium

FIG. 1: Magnetization curves $M_a(H)$ obtained on the YbFeO_3 , sample B, with $H||\mathbf{a}$, at different temperatures.

FIG. 2: Magnetization curves $M_c(H)$ obtained on the YbFeO_3 , sample A, with $H||\mathbf{c}$, at different temperatures.

FIG. 3: Magnetization projections $M_{a,c}(T)$ obtained from the magnetization curves: empty circles - $M_a(T)$ for sample B, empty triangles - $M_a(T)$ for sample A, filled triangles - $M_c(T)$ for sample A.

FIG. 4: Temperature dependence of remnant magnetization along the c -axis. Remnant magnetizations serves as a measure for the width of the hysteresis loops. Increase of hysteresis in reorientation region is clearly seen. The kinks of the curve mark the transition temperatures $T_{1,2}$.

orthoferrites may result from the order of magnitude difference in the temperature of the reorientation transition. This question requires a separate study beyond the scope of the present paper.

The absolute value of magnetization M and rotation angle θ were extracted from the experimental data according to the expressions

$$M = \sqrt{M_a^2 + M_c^2}, \quad \theta = \arctan\left(\frac{M_a}{M_c}\right)$$

and are shown in Fig. 5 and Fig. 6. Experimental results presented in Fig. 3 and Fig. 5 show that as the temperature is lowered from T_N to T_1 , the magnetization of the crystal gradually grows. This reflects the build up of the iron moment near T_N and subsequent development of the ytterbium moment along iron moment⁸ at lower temperatures. In the narrow reorientation region $[T_2, T_1]$ the magnetization rapidly grows almost two-fold. Below T_2 the magnetization continues to grow. This supports the result of Ref. 9, suggesting that the ytterbium moment remains parallel to the iron moment, and does not switch to the antiparallel direction as stated in Ref. 8.

III. THEORETICAL ANALYSIS

Our experimental results can be explained by the modified mean field theory suggested in Refs. 4,5. As the conventional Landau theory,^{1,2,3} the modified theory assumes that the magnetization of iron subsystem is saturated at $T \lesssim T_{1,2} \ll T_N$. The free energy of the iron subsystem is taken in the form

$$F(\theta, T) = F_0(T) + \frac{K_u(T)}{2} \cos(2\theta) + K_b \cos(4\theta). \quad (1)$$

With minimal assumptions about the temperature dependence of phenomenological constants inside the reorientation region, namely constant K_b , and $K_u(T)$ linearly varying with temperature and going through zero inside the reorientation interval, the minimization of the conventional energy functional (1) gives^{1,2,3}

$$\tan \theta = \sqrt{\frac{1+\xi}{1-\xi}}, \quad \xi(T) = \frac{(T_1 + T_2)/2 - T}{(T_1 - T_2)/2} \quad (2)$$

Figs. 5, 6 show that experimental results neither support the constancy of $M(T)$, nor give a $\theta(T)$ dependence consistent with Eq. (2)

According to the modified mean field model, paramagnetic susceptibility of ytterbium subsystem should also be taken into account to adequately describe the magnetic behavior of the orthoferrite. It is assumed, that in the molecular field of iron the rare-earth ion acquires a magnetic moment $\mathbf{m} = \hat{\chi}^{\text{Yb}} \mathbf{F}$, while the absolute value of the iron moment $\mathbf{F}$ remains constant.^{2,8,10,11} Experimentally measured magnetization is the sum of the iron and rare-earth contributions $\mathbf{M} = \mathbf{F} + \mathbf{m}$. The magnetic susceptibility $\hat{\chi}^{\text{Yb}}$ of the rare-earth ions is assumed to be anisotropic. This assumption naturally explains the large change of M inside a narrow temperature interval, since rotation of $\mathbf{F}$ leads to the change of $\mathbf{m}$ and thus changes M as well.⁴ The anisotropy of the rare-earth susceptibility has been reported in the literature.^{2,8,10,11} The key point of Ref. 4 was the proper account of such anisotropy in the calculation of the rotation angle and absolute value of the magnetization, with the result:

$$\tan \theta = r \sqrt{\frac{1+\xi}{1-\xi}}, \quad r = \frac{M_a(T_2)}{M_c(T_1)} \quad (3)$$

$$M = M_c(T_1) \sqrt{\frac{r^2(1+\xi) + (1-\xi)}{2}}. \quad (4)$$

Since $M_a(T_2)$ and $M_c(T_1)$ are measurable magnetizations of the sample at temperatures T_2 and T_1 respectively, the value of r is known and expressions (3) and (4) have no fitting parameters.

According to our measurements, the cubic sample A, for which most of the measurements were done, had $T_1 = 8.0$ K and $T_2 = 6.6$ K. Using the values of $M_a(T_2)$ and $M_c(T_1)$ at these temperatures we find $r = 1.78$. Theoretical curves given by Eqs. (3) and (4) are shown in

FIG. 5: Absolute value of the magnetization $M(T)$ calculated from experimental data. Solid curve - theory Eq. (4)

FIG. 6: Magnetization rotation angle $\theta(T)$ calculated from experimental data in the reorientation region $[T_2, T_1]$ at zero external magnetic field. Solid curve - theory Eq. (3), dash curve - conventional theory Eq. (2)

Figs. 5 and 6 by solid lines. A convincing correspondence between the theory and experiment is evident.

Note, that the analysis of experimental data in terms of the model introduced in Refs. 4,5 is only valid inside the reorientation region. However, it is important that inside the region of its validity such analysis is independent of the driving mechanism of the transition, be it the interactions in the iron subsystem, the R-Fe interactions, the behavior of the rare-earth magnetic susceptibility, or any other process. The approach of Refs. 4,5 only requires the effective anisotropy constant $K_u(T)$ to be a linear function of temperature. Since precisely that behavior of $K_u(T)$ was measured in Refs. 12,13, and Ref. 14 shows that such behavior follows from the microscopic model of Ref. 15, the modified mean field theory^{4,5} can be applicable for a wide variety of orthoferrites.

IV. CONCLUSION

In this paper we report direct measurements of the magnetization absolute value $|M|(T)$ and rotation angle $\theta(T)$ during the $\Gamma_4 \rightarrow \Gamma_{24} \rightarrow \Gamma_2$ spin-reorientation transition in YbFeO_3 single crystals. The results favor the importance of strongly anisotropic rare-earth contribution to the magnetization of the material. They give a convincing argument in favor of the spin reorientation model suggested in Ref. 4 and its applicability to Γ_4 (G_x, F_z) $\rightarrow \Gamma_{24}$ (G_{xz}, F_{xz}) $\rightarrow \Gamma_2$ (G_z, F_x) orientation transitions in different materials.
